Introduction

DTI tractography methods generate streamlines that correlate with the orientations of the neural fibers in the white matter. Researchers studying neuroanatomy label white matter with fiber tracts comprised of groups of neural axons running in proximity to one another. These tracts provide a useful abstraction of the white matter structures; they can be used for identification and quantification of neural fibers. However, due to variation across subjects in white matter, labeling these fiber tracts by hand can be time-consuming and error-prone. Taking advantage of the proximity property, we can automatically cluster the fiber tracts from the path set generated from a brain DTI data set. The task becomes more challenging when we cluster the paths over the entire brain instead of a region of interest since no human input of the tract information will be implied. We present our experiments in unsupervised clustering of a dense set of fiber paths generated from a whole brain DTI data set.

Related Work

Ding et al. [1] proposed DTI fiber classification and quantification. They defined a corresponding segment ratio and employed that ratio together with the mean distance over the corresponding segments to delineate the similarity between two streamlines. The similar streamlines whose seeding points are near the original streamline seeding point are grouped into a bundle.

Corouge et al. [2] proposed a clustering algorithm that propagate the cluster to the neighboring fibers. They also employed three distance measures based on the point sets on the pair of streamlines.

We used a similar clustering algorithm on a dense set of paths over the whole brain. Early results showed that a lack of paths within a tract or spurious paths between tracts can lead to possible false classifications. We propose strategies in setting seeding points, path constraints, culling distance and setting distance metrics to minimize the misclassifications.

Method

Generating paths

The head of a normal volunteer was imaged in a Siemens Symphony 1.5T scanner. Three slice packets were acquired sagittally and interleaved to acquire a data volume of $128 \times 128 \times 90$ with a voxel size of $1.7 \times 1.7 \times 1.7$ mm. The Siemens MDDW protocol was used, with three $b$ values (0, 500, 1000) in 12 directions.

We put seeding points on a regular grid every 0.85 mm with small jittering. When the seeding distance is below 1.3 mm, doubling the number of the seeding points results in an almost constant increase in the number of paths. This indicates that our sampling of the paths in the white matter is sufficiently dense to avoid missing links between paths in the same tracts.

We used the streamtube algorithm [3] to generate streamlines from these seed points. The integration stops when the linear
anisotropy value is below 0.15, the streamline transcends the data boundary, or the signal-to-noise ratio provided by T2-weighted image is below a certain threshold. The initial path set is shown in Fig. 4 left. Since some of the paths might cause artificial linking as shown in Fig. 3 left, we set a threshold on the average linear anisotropy along the path in order to remove paths that are in ambiguous regions. We also remove the paths that are too similar. Some paths stop within ambiguous regions in the white matter. They can be considered spurious paths and might cause artificial linking between anatomically unrelated tracts. We cull again to remove those paths that do not project into the gray matter. The paths after the culling process are shown in Fig. 4 right.

The minimum distance between any two paths from two clusters is used for the distance between these clusters, the method is called the nearest-neighbor cluster algorithm, or minimum algorithm.

**Results**

Figure 4 shows the streamlines before clustering. The left picture shows the path set without the endpoints constraint. There are about 1,100 paths, many of which are short paths that stop within the ambiguous white matter regions, which could potentially create artificial links between fiber bundles. The right picture shows the 6,000 paths after the culling process. Fiber bundles in Fig. 1 and Fig. 2 are clustered on this path set. There are 600 bundles; we only visualize around 100 bundles that contain 10 or more paths.

From the top view of our model (Fig. 1), the two cingulum bundle tracts are clearly indicated as two clusters; the corpus callosum form several bundles that run into the outer brain without much divergence within the bundles. Groups of U fibers also form distinct bundles. From the side view (Fig. 2), the internal capsule is clustered into several bundles that are coherent along the pathways.

**Conclusion**

We present a clustering process for the fiber paths from a whole brain DTI data set. We propose a path culling process and a similarity metric for the clustering algorithm to avoid misclassifications. The results show that in most places, paths are grouped together in coherent bundles.
